Abstract—Untrusted third-party vendors and manufacturers have raised security concerns in hardware supply chain. Among all existing solutions, formal verification methods provide powerful solutions in detection malicious behaviors at the pre-silicon stage. However, little work have been done towards built-in hardware runtime verification at the post-silicon stage. In this paper, a runtime formal verification framework is proposed to evaluate the trust of hardware during its execution. This framework combines the symbolic execution and SMT solving methods to validate the user defined properties. The proposed framework has been demonstrated on an FPGA platform using a SoC design with untrusted IPs. The experimentation results show that the proposed approach can provide high-level security assurance for hardware at runtime.

I. INTRODUCTION

The changing landscape of the semiconductor industry has increased the demand for third-party intellectual property (IP) cores. Various factors such as reduced time to market (TTM) and lower design cost have led to the proliferation of the IP market. Another contributor to this growth is the use of System-on-Chip (SoC) platforms for mobile applications. SoC is a monolithic chip containing all the essential components for mimicking the functionality of a computing system. It is designed by integrating multiple IP cores from trusted and untrusted third party vendors.

Increasing number of third-party vendors have raised security concerns in the IC industry. Due to the extremely high cost of building foundries, chip manufacturing is usually outsourced to existing foundries. Therefore, a comprehensive approach is required to protect against attacks from untrusted vendors and manufacturers. Formal methods have shown their importance in exhaustive hardware security verification [1]-[4], but few of them were designed for securing post-fabrication designs. For example, in [2]-[4], the proof-carrying hardware (PCH) framework was used to verify security properties of soft IP cores. Supported by the Coq proof assistant [5], formal security properties were formalized and proved to ensure the trustworthiness of IP cores. However, model formalization and interactive proof procedures in PCH limit the scenario into static verification for design stage in the supply chain.

In this paper, we address the runtime hardware security verification challenge by extending our Proof-Carrying Hardware (PCH) [3], [4], [6] framework from static to dynamic (aka runtime) with a SMT solver and symbolic executions. The working procedure of the developed runtime

Fig. 1: Working procedure of runtime PCH framework

PCH framework is shown in Figure 1. The main contributions of this paper are as follows.

- We combine a SMT solver with a static program analysis method for runtime checking of security of hardware.
- The work improves the study of hardware runtime verification. Our enhanced PCH framework provides comprehensive protection of hardware by complying to user specified security properties.

II. BACKGROUND AND RELATED WORK

A. Attack Model

Hardware Trojans/Malicious logic can be inserted by adversaries at the different stages of the IC life-cycle. We assume that the rogue agents at the third-party IP design house and foundry can insert a hardware Trojan or backdoor to the fabricated circuit. Such a Trojan can be triggered either by a counter at a predetermined time, by an input vector, or under certain physical conditions. Upon activation it can leak sensitive information from the chip, modify functionality, or cause a denial-of-service to the hardware.

B. Related Work

In [3], [4], [6], the proof-carrying hardware (PCH) framework was used to verify security properties of soft IP cores. Supported by the Coq proof assistant [5], formal security properties were formalized and proved to ensure the trustworthiness of IP cores. However, this framework can only provide static verification on design stage of hardware other than the runtime of hardware. In [7], a SAT solver is utilized
to enhance the PCH to be applicable in runtime scenario. Still, expressiveness of the SAT solver is not powerful enough so that security properties are difficult to be formalized in such framework.

Verifiable ASICs was proposed by Wahby et.al. [8] to verify the correctness of functionality of hardware system. In their paper, runtime (or dynamic) verification was performed by implementing an interactive encryption protocol between untrusted ICs and a second trusted ICs, where the untrusted ICs was called Prover and trusted ICs was called Verifier. It was the first attempt to compute proofs of correct execution through utilizing verifiable computation. However, for security purpose, their correctness checking method would result in high computational cost and overhead. Furthermore, their method was designed for checking specific property rather than the entire set of functional properties.

C. Background

Satisfiability (SAT) solvers have been used in many electronic design automation fields like logic synthesis, verification, and testing. The SAT solvers are originally designed to solve the well-known Boolean Satisfiability problem, which decides whether a propositional logic formula can be satisfied given value assignments of the variables in the formula. Based on SAT solver, satisfiability modulo theories (SMT) solver is derived by including several first-order theories, such as arithmetic, bit-vectors, quantifiers, etc. [9]. However, due to the high computational complexity, there is no hardware implementation for SMT solvers, and the software based SMT solver are not scalable to large designs.

Symbolic execution is a program analysis technique that can explore multiple paths that a program could take under different inputs [10]. In this method, execution paths that the program should take are explored systematically to avoid the space explosion problem. Specifically, inputs are represented as symbols and the solvers are used to check whether there are counter examples of the property. For each path, a Boolean formula is derived to describe the conditions of the branches, while a symbolic memory is used to map variables to symbolic expressions. The Boolean formula is updated after executing the branch and the symbolic memory is updated after each assignment. Integrating these two techniques overcome the NP-Hard computation complexity issue in SAT solver and it provides a comprehensive protection by automatically checking the customized properties.

III. Runtime Proof-Carrying Hardware

In this paper, we give a solution for hardware runtime formal verification of security properties. The proposed runtime PCH framework integrates a static program analysis method and a hardware based SMT solver, and provides a high-level protection by verifying security properties defined by users.

In detail, a trusted circuit is designed and manufactured by a trusted foundry to verify the trustworthiness of the untrusted hardware in runtime. Similar to [8], in our propose of new PCH framework, the untrusted circuit from the third-party foundry is called Prover, while the trusted circuit is called Verifier as shown in Figure 1. If the verification of the security properties/theorem is successful, it indicates that the Prover is trustworthy. Further, Verifier can get all the information from Prover. In the case where the verification fails, the Verifier can disable the Prover at anytime.

There are mainly two entities - untrusted foundry and trusted integrator interacting in the developed framework (see Figure 1). At first, the untrusted foundry gets requirements of ASICs from consumer, and then fabricates the chips as part of Prover depending on the functionality specifications, which is golden model in Figure 1. The other part of Prover produces a conjunctive normal form (CNF), which is a combination of proof and secure specifications. The CNF will be delivered from Prover to the solver, and satisfaction of the CNF will be checked. If satisfied, then the execution of circuit will be continue. If the given CNF is unsolved, then the Verifier will lock the circuit. Accordingly, the trusted integrator, on the side of consumer, designs an extra trusted circuit Verifier that can provide verification of Prover on runtime and then combine Verifier and Prover together to produce the runtime verification system S. The composition of the final system S can be presented as Equation (1).

\[ S := P \lor V \]  

Further, the trusted integrator explores execution paths from static program analysis of the functional golden model written by hardware description language (HDL) like Verilog. In the untrusted foundry side, each execution path will be manufactured individually, and we call them individual circuit segment, marked as \( \text{seg} \). So we define the functionality of circuits inside the \( P \) as \( F \) and then \( F \) is composed of many \( \text{seg} \) as shown in Equation (2), where \( k \in Z \) is the total number of segments.

\[ F := \text{seg}_1 \land \text{seg}_2 \land \cdots \land \text{seg}_k \]  

Correspondingly, security property, defined as \( \text{Prop} \), would be given by the integrator and then decomposed into sub security properties, defined as \( \text{lemma} \). In Verifier side, satisfaction of each sub property \( \text{lemma} \) will be verified for the corresponding segment \( \text{seg} \) as shown in Figure 2. So the system level security property \( \text{Prop} \) is constructed as Equation (3).

\[ \text{Prop} := \text{lemma}_1 \land \text{lemma}_2 \land \cdots \land \text{lemma}_k \]  

Along with the \( F \), untrusted foundry requires to give proof to satisfy \( \text{lemma} \) for each \( \text{seg} \), and the proof is given in form of CNF, defined as \( \text{cnf}_{\text{seg}} \) in Equation (4) where \( n \in Z \) stands for index number of a list, \( \text{Tsetit} \) is a transformation that converts boolean circuits to CNF [11].

\[ \text{Tsetit} \]  

\[ \text{seg}_n \longrightarrow \text{cnf}_{\text{seg}_n} \]  

661
Meanwhile, \textit{lemma} need to be parsed to a hardware expression \textit{lemma}_{expr} that can be represented by using HDL. In our proposed framework, parsing is made manually in the foundry side. After that, a \textit{Tsettin} transformation is utilized to convert the \textit{lemma}_{expr} to a CNF, noted as \textit{cnf}_{lan}. The procedure is presented in Equation (5).

\[ \text{lemma}_n \xrightarrow{\text{parse}} \text{lemma}_{expr} \xrightarrow{Tsettin} \text{cnf}_{lan} \quad (5) \]

Therefore, proof of sub property for segment is defined as a conjunction of \textit{cnf}_{seq} and \textit{cnf}_{lan} as shown in Equation (6). Furthermore, the entire proof in system level, noted as \textit{CNF}, is composed of all the distributed \textit{cnf}_n as described in Equation (7).

\[ \text{cnf}_n := \text{cnf}_{seq} \land \text{cnf}_{lan} \quad (6) \]

\[ \text{CNF} := \text{cnf}_1 \land \text{cnf}_2 \land \cdots \land \text{cnf}_k \quad (7) \]

Finally, in the following Equation (8), \textit{Prover} is constructed from functionality part \textit{F} and proof part \textit{CNF}. In the runtime verification process, \textit{cnf}_n would be put into the DPLL SAT solver and verified individually. The verification details will be discussed in the following part.

\[ P := F \land \text{CNF} \quad (8) \]

A DPLL SAT solver is implemented based on Algorithm 1. A typical existing SMT solver is constructed based on the SAT solver, which is shown in the Figure 4. Specifically, in the proposed framework, the SMT solver is developed to get the extra constrains from a high level, while the \textit{CNF} is input to the SAT solver directly. In the verification, Proof \textit{cnf}_n is delivered from \textit{Prover} to the solver, and satisfaction of the input \textit{cnf}_n will be checked. If satisfied, then the \textit{Prover} will lock the segment by using an AND gate.

Algorithm 1 DPLL Algorithm

Input:
1. \textit{F} \text{ A CNF formula.}

Output: \textit{Result} \text{ A Boolean value where True stands for satisfaction and False stands for not-satisfaction.}

2. Preprocess \textit{F};
3. if \textit{F} == False then
4. \text{Result} \leftarrow False; return;
5. end if
6. Find the next unassigned variable, assign the value;
7. Deduce based on the assignment;
8. if \textit{F} == False then
9. \text{Result} \leftarrow False; return;
10. end if
11. if The conflict happened in derivation then
12. Analyze the conflict
13. if \textit{F} can be looked back upon then
14. look back upon
15. else
16. \text{Result} \leftarrow False; return;
17. end if
18. else
19. return to line 6.
20. end if

Except the segment and CNF block, the rest part of Figure 3 depicts the design of the \textit{Verifier} which comprises a LUT and a DPLL SAT solver. The LUT in the proposed framework records information that whether the segment has been verified or not. The LUT includes two columns, where the first column contains a segment list and the second column has a binary value for each segment i.e. 1 stands for verified, 0 stands for not verified. Before the execution of a segment, the corresponding value will be checked. If the segment has been verified, then the execution continues. Otherwise, the system will be stalled and the verification of the segment is performed first.
As a result, the SAT solver (kernel of the proposed SMT solver) took $4668406745$ clock cycles or $9sec$ (2ns per clock cycle based on our configuration) for returning an unsatisfaction conclusion for the proof/CNF of initial assignments segment, which indeed contains the Trojan. Meanwhile, the SAT solver took $7873$ clock cycles or $15ms$ for returning a satisfaction conclusion for the same segment without Trojan.

V. Conclusion

In this paper, we give a solution for hardware runtime formal verification of security properties. The proposed runtime PCH framework integrates a static program analysis method and a SMT solver, and provides a high-level protection by verifying security properties defined by users. The proposed method was demonstrated using FPGA and evaluated by verifying a RS232 benchmark with an embedded Trojan. Consequently, the proposed approach guarantees the security of hardware in runtime.
